Abstract

In clinical medicine, increasing attention is being directed towards the important areas of nutritional biochemistry and toxicant bioaccumulation as they relate to human health and chronic disease. Optimal nutritional status, including healthy levels of vitamin D and essential minerals, is requisite for proper physiological function; conversely, accrual of toxic elements has the potential to impair normal physiology. It is evident that Vitamin D intake can facilitate the absorption and assimilation of essential inorganic elements (such as calcium, magnesium, copper, zinc, iron and selenium) but also the uptake of toxic elements (such as lead, arsenic, aluminum, cobalt and strontium). Furthermore, sufficiency of essential minerals appears to resist the uptake of toxic metals. This paper explores the literature to determine a suitable clinical approach with regards to vitamin D and essential mineral intake to achieve optimal biological function and to avoid harm in order to prevent and overcome illness. It appears preferable to secure essential mineral status
in conjunction with adequate vitamin D, as intake of vitamin D in the absence of mineral sufficiency may result in facilitation of toxic element absorption with potential adverse clinical outcomes.

Key words: vitamin D, essential minerals, toxic elements, heavy metals, calcium, magnesium, selenium, zinc, iron, copper
Vitamin D, Essential Minerals and Toxic Elements:
Exploring Interactions between Nutrients and Toxicants in Clinical Medicine

Introduction

The medical literature has achieved general consensus that Vitamin D levels throughout much of the world, as reflected by population measurements of \(25(\text{OH})D_3\) levels, are generally inadequate.[1] About 2/3 of the population in northern climates are considered deficient with average \(25(\text{OH})D_3\) levels of 67nmol/l, [2] much below the 100 - 150nmol/l level that has recently been associated with preferred health.[3] There are many papers emphasizing the benefits of supplemental vitamin D in order to achieve levels that are protective for many diseases.[4, 5] There has been recent concern expressed, however, that consumption of excessive doses of supplemental vitamin D may pose certain risks and potentially confer harm to individuals. With recognition that vitamin D intake can also facilitate the uptake of toxic elements, the objective of this review paper is to explore known interactions between vitamin D, essential minerals and toxic elements in order to provide clinical recommendations regarding the supplemental use of this important vitamin.
This review was prepared by assessing available medical and scientific literature from Medline, as well as by reviewing several books, nutrition and toxicology journals, conference proceedings, government publications, and environmental health periodicals. A primary observation, however, was that limited scientific literature is available on the issue of Vitamin D in relation to essential and toxic elements. The format of a traditional integrated review was chosen as such reviews play a pivotal role in scientific research and professional practice in medical issues with limited primary study and uncharted clinical territory.[6]

**Vitamin D adequacy and safety**

As Vitamin D acts epigenetically in the regulation of over 2700 different genes by acting on vitamin D responsive elements,[7] it is not surprising that considerable literature confirms the necessity of achieving adequate \(25(\text{OH})\text{D}_3\) in order to attain optimal health. A recent article suggests \(25(\text{OH})\text{D}_3\) levels \(>30\text{nmol/l}\) have significantly lower all cause mortality than levels \(<30\text{nmol/l}\).[14] Levels above 78 nmol/L are considered beneficial for bone health and maintaining normal parathyroid hormone[8]. Cancer prophylaxis may not be fully realized until levels are over 90nmol/l.[9] Benefits in countering infections such as tuberculosis and influenza may require levels of over 100 nmol/l[10] and levels at or above 120 are associated with the lowest mortality. [3]
While there is abundant evidence confirming potential harms associated with deficient vitamin D, as well as much research displaying the enormous benefits of supplementation to replete and maintain adequate vitamin D indices, [11] uncertainty has arisen regarding levels that are considered too high. A recent article, for example, showed increased 90 day mortality rates in hospitalized patients with pre-admission levels of 25(OH)D$_3$ <50nmol/l or >150nmol/l.[3] Such findings have raised concern that levels of 25(OH)D$_3$ greater than 150nmol/l may not be optimal. This U shaped phenomenon of benefit only within a specific range and risk outside of this range has been suggested in other articles as well. The risk for pancreatic cancer, for example, allegedly increases at higher vitamin D levels [12] but on further analysis this finding may have been a statistical artifact due to the chosen cut-off point groupings.[13]

The risk of potential harms associated with higher levels, however, is dismissed by others with the contention that 25(OH)D$_3$ levels of 225 nmol/l can be achieved with ordinary sunlight and are thus considered normal. Furthermore, levels of <375nmol/l have been shown in some research to not result in any evident toxicity.[15] In review, there is insufficient study of supplementary doses of vitamin D which result in 25(OH)D$_3$ levels higher than 150nmol/l to make firm conclusions. Just the same, there has been preliminary exploration of pathophysiological mechanisms that might account for potential risks associated with higher 25(OH)D levels.
Vitamin D and inorganic elements

One point of note is that adequate 25(OH)D₃ is associated with improved absorption of essential elements including calcium, magnesium, iron, phosphate, zinc and copper. What has largely been forgotten, however, is that higher levels of 25(OH)D₃, have been linked to enhanced absorption of toxic elements such as aluminum, cadmium, cobalt and lead as well as radioactive isotopes including cesium and radioactive strontium. It has also been observed in the chick that vitamin D increases zinc and cadmium absorption. In children elevated 25(OH)D₃ in the summertime are associated with a seasonal increase in blood lead levels via increased intestinal absorption. It is also well recognized that bioaccumulation of such toxic metals in turn appears to disrupt physiological functioning of Vitamin D within the body. For example, accrual of lead or cadmium diminishes the activity of Vitamin D, by blocking the normal renal synthesis of active 1,25 dihydroxyvitamin D. There is also evidence discussed in the literature of myriad adverse effects that various toxic metals including cadmium, lead, mercury and aluminum can have on normal biological processes including uptake, absorption, and assimilation of assorted essential minerals – which may consequently result in health problems. Toxic metals themselves can also accrue in various tissues and have been directly linked to various adverse health outcomes. Table 1 provides an overview of the complex interaction between vitamin D and various inorganic elements – both required minerals and toxic metals.
The question therefore arises as to whether the alleged rise in morbidity and mortality associated with elevation of 25(OH)D₃ (>150nmol/l) may be, in part, associated with the increased accumulation of toxic metals – a common concern in contemporary society.[24] To the authors’ knowledge, however, no studies have been done to date which measure accrued levels of toxic metals in population groups in direct relation to 25(OH)D₃ levels. One of the challenges with the assessment of this hypothesis is that much of the reported bio-monitoring of toxic elements in population groups has been confined to unprovoked blood or urine levels of toxicants – which often underestimate the body burden. Most toxic elements and compounds tend to sequester in tissues and may not be evident on blood or urine testing.[25] Lead, for example, may be abundant in bone and brain where it tends to accumulate, with potentially little evidence of such accrual with blood or urine testing.[26]

It is also evident that vitamin D does not act solely in isolation. Impaired vitamin D functioning and insufficient levels of essential minerals can have synergistic and cumulative adverse action on biological function with significant pathophysiological impact. For example, vitamin D metabolism is dependent on sufficient magnesium as a cofactor for vitamin D to bind to its transport protein and for this vitamin to convert into the active form via hydroxylation in renal and hepatic
sites.[27] Furthermore magnesium deficiency may up-regulate the 24(OH)ase enzyme in the kidney resulting in catabolism of vitamin D.[27] Insufficiency of magnesium has been associated with many adverse clinical effects including depression,[28] anxiety,[29] cardiac problems [30] and has recently been found to be associated with impaired immune function[31] and to inversely affect C-reactive protein.[32] It is estimated that more than 68% of US adults are consuming levels of magnesium below the recommended daily allowance(RDA).[33] Factors that may enhance magnesium deficiency, states such as accrued toxic metals possibly resulting from elevated vitamin D in the absence of sufficient minerals, may thus have an impact on metabolic function.

Furthermore, any determinant such as accrued toxic metals that would exacerbate zinc deficiency also has a potential detrimental impact on physiological function. Along with iron, boron, manganese and copper, the essential mineral zinc is important as a cofactor in bone health. Specifically, zinc facilitates bone formation by stimulating the osteoblast.[34] While the average daily intake of zinc is considered to be only 46-63% of the RDA, various toxic metals have a detrimental impact on zinc uptake into the body. [Table 1] Additionally a study on mineral content of foods has found that more than 80% of Americans do not achieve the RDA or the estimated safe and adequate daily dietary intake of calcium, magnesium, copper, zinc and iron. The result of such widespread deficiency may be increased risk of toxic element absorption.[35]
The complex interaction between the essential element calcium, vitamin D, and toxic metals is also evident in various reports from the literature. [Table 1] While no more than 800mg of calcium a day may be required when vitamin D levels are adequate, the typical diet in North America may be inadequate to supply even this limited amount. [36] Furthermore, as is noted in Table 1, toxic metals may impair calcium uptake resulting in deficiency states. While much recent attention has been devoted to the finding that excess calcium intake may actually cause harm – increasing the risk of myocardial infarction by 31% and stroke by 20%,[37] – it is important to remember that sufficiency of calcium is required for normal physiological function, a clinical state that may be compromised by vitamin D insufficiency or toxic metal bioaccumulation.

**Vitamin D Supplementation**

Adequate sun exposure in warmer climates or consumption of vitamin D containing foods such as fatty seafood in northern areas has traditionally been the preferred means to achieve adequate vitamin D status. However, higher latitudes experience ultraviolet B sunlight intensities that are too weak for extended periods to induce sufficient vitamin D skin synthesis. Furthermore, insufficient consumption of vitamin D containing foods frequently occurs because of dietary preference, or avoidance because of concern about toxicant accrual in foods such as mercury in fish. As a result, vitamin D supplementation is
being encouraged from many sources as a means to secure adequate intake in order to maintain optimal biological functioning.

With adequate sunlight and food consumption, it appears that there are natural mechanisms to secure preferred vitamin D levels and to prevent excessive bioaccumulation. With sun exposure, for example, enzyme down regulation appears to occur as higher levels are achieved so that diminished vitamin D skin production, absorption and assimilation occurs.[38] This inherent protective approach, however, may not be evident with supplemental intake of isolated vitamin D ingestion. With supplementation particularly for populations living in more northern latitudes, how does one secure an optimal vitamin D levels in clinical settings without exceeding healthy levels?

Just as one might measure specific indices such as hemoglobin or potassium levels in patients inclined to be low in these biochemical markers, monitoring of individual 25(OH)D levels in clinical settings is the preferred way to secure an optimal vitamin D status in individual patients. As there is variation in response to vitamin D supplementation as a result of factors such as weight and toxicant levels that influence uptake and absorption of vitamin D, measurement is the only way to confirm optimal vitamin D status, to ensure compliance with instructions, and to preclude excessive or dangerous levels. While there
have been many studies that confirm the benefits of vitamin D supplementation in specific groups, [4, 5] there has been a paucity of studies that actually measure individual levels in population groups after a specific level of supplementation.

The varied response to specific levels of vitamin D supplementation is evident in one such study- a nursing home study supplementing with 2,000IU daily for more than 5 months. [Table 2] The residential population with an average age 80.7 (N=68) achieved an average 25(OH)D level of 119.3nmol/l with this level of vitamin D ingestion. [39] Further analysis of this data reveals that 12 patients or 22% achieved levels less than 100nmol/l, but that 6 patients or 9% reached levels of > 150nmol/l. At this level of supplementation about 6% of patients would not achieve levels considered necessary for good bone health at 78nmol/l but only 78% would have levels between 100 and 150 nmol/l. It appears that about 4000IU of vitamin D might be required to allow a significant portion of the population to achieve the desired 100-150nmol/l. With this level of supplementation, none of the participants would reach a commonly accepted dangerous 25(OH)D level of >375nmol/l.

In another study [Table 2] of the general population(N=1430) at a northern latitude[2], projections were made based on average responses to specific levels of vitamin D supplementation. In this report, only 22% of the 1430 patients were found to have levels between 100 and 150nmol/l. Within the 1% of patients found to have levels over 150nmol/l of 25(OH)D₃, more
than 73% admitted to pronounced levels of sun exposure, regular artificial sun tanning at tanning studios, or both. The highest level recorded was 216nmol/l in a patient that had both sun exposure and was sun tanning. Once again, none of the participants reached levels anywhere near or >375nmol/l.

In addition, a recent risk assessment for vitamin D toxicity with supplemental doses found no evidence of toxicity using 10,000IU daily for a six month period.[40] As a result of the evident safety of using considerable supplemental doses of vitamin D, the Institute of Medicine (IOM) has recently raised the maximum allowable amount of vitamin D to 4000IU daily with no required monitoring for toxicity.[41] With variation in response to specific doses of supplemental vitamin D, monitoring of 25(OH)D levels with required dose adjustments appears to be the most effective means to secure adequacy and to preclude excessive levels.

**Clinical implications**

There has been much debate in the medical literature about the preferred level of 25(OH)D, the optimal level of supplementation, and the degree of intake or levels that might be dangerous. In the medical literature as a whole, many researchers suggest that measured levels of 25(OH)D should ideally remain within the 100 and 150nmol/l range.[42] This
view is endorsed by the Vitamin D Society as lower levels are associated with inferior human health outcomes and higher levels might have the possibility of increasing risk of morbidity and mortality. As mentioned, some recent information suggests that vitamin D intake to achieve a minimum level of 120nmol/l is associated with the lowest mortality,[3] a recommendation that has been adopted by groups such as the ‘Vitamin D Council’ and ‘Vitamin D Society’. A recent Endocrine Society recommendation suggests targeting for a 25(OH)D level value greater than 75nmol/l. In order to ensure that individuals “true” 25(OH)D is greater than 75nmol/l, they suggest aiming for a value of 100nmol/l, a level that is not associated with toxicity. [43]

Conversely, however, some prominent medical groups have differed in their recommendations. While the IOM (Institute of Medicine) agrees that 4,000IU of vitamin daily is allowable and non-toxic, the actual recommended daily dose by this group is 600IU daily.[41] This IOM recommendation has been put into question[44] as a significant statistical error has been identified in the way the recommendation was arrived at.[45] Furthermore, the IOM recommendations have been refuted by a study suggesting that it may take as much as 8800IU of vitamin D daily to bring 97.5% of the population to levels of 50nmol/l,[45] far shy of what most deem to be optimal.
Because of practical concerns such as expense associated with testing, nonetheless, some have suggested that there is no point determining and following 25(OH)D measurements, with the rationale that most individuals are low and should simply be taking regular vitamin D supplementation. But the degree of supplementation will vary based on geographic area, degree of sun exposure, nature of the diet, level of toxicants, and so on. Annual testing has long been suggested for this reason.[5] Accordingly, while it is increasingly suggested that a certain range of 25(OH)D may be associated with preferred health outcomes, there may be huge differences in the required intake of supplemental vitamin D to achieve a specific 25(OH)D endpoint. For example, populations at higher latitudes would require significantly more supplemental vitamin D in order to achieve levels above 100nmol/l compared to those living in warm sunny climates. Accordingly, annual bio-monitoring of 25(OH)D levels are suggested when possible as the health benefits and resultant cost savings should far outweigh the expense of annual testing. The savings in health care dollars has been estimated to be in the range of 14 billion dollars in Canada,[46] 187 billion in Western Europe[47] and 56 billion in the United States.[48] Essentially, it is estimated that the cost of bio-monitoring would be about 5% of the cost savings.

Sufficiency of vitamin D has implications for other essential nutrients as this important vitamin is recognized to interact and maintain physiological function in concert with other vitamins and minerals. As discussed, absorption of essential minerals
and toxic metals are all increased with more vitamin D, and insufficient levels of various essential minerals appear to facilitate toxic metal absorption [Table 1]. The majority of Americans, however, receive insufficient magnesium [49] largely due to the processing of foods where magnesium levels are reduced by as much as 400%. [50] Evidence suggests that intake of other essential minerals is also inadequate in many situations, resulting in a higher risk of toxic metal absorption. Hospitalized patients, for example, are prone to mineral deficiencies, particularly in the intensive care units. [51] Accordingly, in order to achieve an optimal vitamin D status and to minimize the risk of toxic element accumulation, securing intake of essential minerals through foods or supplementation in addition to adequate vitamin D levels is fundamental to achieving optimal health outcomes.

**Conclusion:**

Several clinical recommendations are in order based on the presented information from the literature. Population studies across the world report low levels of vitamin D. Lifestyle changes and adequate supplementation are required to achieve optimal 25(OH) levels - thought to be about 100-150nmol/l. From the studies listed in table 2 it is evident that the average population in a country such as Canada with little natural UVB stimulation for >6 months of the year, only 22% of the
population achieve levels to confer all the benefits (bone and non-bone) of vitamin D adequacy. Likewise supplementing with 2000IU would achieve adequate levels in less than about 78% of the population. Blood monitoring is recommended on a yearly basis with sufficient supplementation to secure optimal levels (25(OH)D levels >100nmol/l) as outlined above.[5] Such an approach would realize enormous savings of healthcare resources across the world.

It is important to recognize that vitamin D does not work alone but requires essential minerals to achieve its full benefit. Deficiency of minerals including magnesium, calcium, zinc and iron are very common as outlined above. Recognizing the synergistic action of mineral deficiency with elevated vitamin D levels on the uptake of toxic elements, adequate intake of minerals needs to be ensured.

It is possible that the concern associated with excessive vitamin D might be explained by the increased absorption and bioaccumulation of toxic elements. Further study is required to explore this emerging concern. Just the same, efforts to reduce exposure to and accrual of toxic elements such as the diminution of emissions of toxic elements by industry are also indicated. This would reduce contamination by toxic elements in the air we breathe as well as deposition in soil and uptake into
consumed foods, thus diminishing the risk of exposure and uptake of toxic metals, regardless of levels of vitamin D and essential minerals.

Finally, there is preliminary evidence that higher morbidity and mortality may be associated with excessively elevated vitamin D levels. This problem may be exacerbated by a deficiency of essential minerals, potentially resulting from inadequate dietary intake or the result of accumulated toxic elements. Therefore, efforts to secure mineral adequacy, to avoid toxic metal exposure, and avoidance of potentially excessive Vitamin D intake are suggested.

*All levels achieved in these patients were well below 375nmol/l where side effects have been reported.

**KEY POINTS:**
i) Vitamin D sufficiency as reflected by a 25(OH)D level of about 100-150nmol/l may be an optimal clinical endpoint, although controversy remains over the ideal level. Taking into account the vast number of population studies, both in temperate and equatorial climates, population levels are quite low in many jurisdictions and supplementation is recommended to achieve optimal levels.

ii) The IOM daily recommendation of 600 IU of Vitamin D3 for adults <70 years old would not achieve these preferred levels in more than 50% of people and thus the IOM recommendation has been called into question as outlined above.

iii) Sufficiency of essential minerals is necessary to prevent bioaccumulation of toxic elements and to enhance activation of vitamin D related proteins.

iv) Excessive vitamin D intake may have detrimental effects, perhaps by enhancing the absorption of toxic elements.

v) Levels of vitamin D supplementation required to reach optimal endpoints will vary depending on myriad factors and thus a single recommended dose for all may not be an optimal approach to secure vitamin D adequacy.
